Constraints in household relocation: Modeling land-use/transport interactions that respect time and monetary budgets

Abstract: Traditionally, integrated land-use/transportation models intend to represent all opportunities of travel and household location, maximize utilities and find an equilibrium in which no person or household could improve their satisfaction any further. Energy scarcity, higher transportation costs and an increasing share of low-income households, on the other hand, demand special attention to represent constraints that households face, rather than opportunities for utility maximization. The integrated land use model SILO explicitly represents various constraints, including the price of a dwelling, the travel time to work and the monetary transportation budget. SILO ensures that no household makes choices that violate these constraints. Implementing such constraints helps SILO to generate more realistic results under scenarios that put current conditions under a stress test, such as a serious increase in transportation costs or severely increased congestion.

1 Introduction

Households looking for a new place to live attempt to fulfill as many of their location preferences as possible. At the same time, however, households face a couple of constraints in housing search. First and foremost, the price of a new dwelling is a constraint. Even though loans and mortgages allow households to afford places that exceed their immediately available budget, households have to get along with their income in the long run. This is why low-income households cannot afford moving into the most sought-after houses on the market. Income is an obvious constraint on housing choice for almost every household.

Another constraint households face when looking for a new dwelling is travel time. An analysis of the 2007-2008 Household Travel Survey for the Baltimore/Washington region revealed that 86% of all workers travel less than 60 min to work, and 99% travel less than 120 min to work. Commuting for no more than two hours, therefore, is another constraint for most households, at least on a daily basis.
Suitable home locations are even more restricted if more than one household member is working. As the average time spent on commuting does not change much over time (Zahavi et al., 1981), this constraint is unlikely to change much in the future. As a consequence, the average workers should be expected to move closer to their work location if congestion worsens, unless they have the opportunity to telework.

Another constraint is constituted by the total household budget. According to the Consumer Expenditure Survey\(^1\), the average U.S. household spends 18.2\% of its after-tax income on transportation. Should transportation become more expensive, households have to either adjust their travel behavior or reallocate their income. In reality, both happen. In some cases, particularly for low-income households, a steep increase in transportation costs may trigger a household relocation to a less expensive apartment to ensure that the household gets along with its income in the long run.

The literature review (section 2) shows that the majority of land-use models do not represent such constraints explicitly. Section 3 introduces the land-use model SILO, and section 4 explains how constraints are treated in SILO. Section 5 shows model validation results and section 6 ends this paper with conclusions and recommendations for further research.

### 2 Literature review

One of the pioneering land-use models was designed by John D. Herbert and Benjamin H. Stevens (1960) in cooperation with Britton Harris as an equilibrium model simulating the distribution of households to residential land use. Lowry’s Model of Metropolis (Lowry, 1964, Lowry, 1966) is often considered to be the first computer model that truly integrated land use and transportation. The Lowry Model assumed the location of basic employment exogenously and generated an equilibrium for the allocation of non-basic employment and population. Over the last five decades, this popular model has been implemented many times (e.g., Batty, 1976, Wang, 1998, Mishra et al., 2011). At least equally influential was Forrester’s Theory of Urban Interactions (1969). Even though it was an aspatial model, his research on interactions between population, employment and housing has influenced the design of many spatial land use models developed ever since.

Putman developed the Integrated Transportation and Land Use model Package (ITLUP) (Putman, 1983, 1991), where land use was modeled by the Projective Land-Use Model (PLUM) (Rosenthal et al., 1972, Goldner et al., 1972, Reynolds and Meredith, 1972). Later, PLUM was replaced by the frequently applied Disaggregated Residential Allocation Model (DRAM) and an Employment Allocation Model (EMPAL).

\(^1\) Available online at http://www.bls.gov/cex/#tables
Wilson’s Entropy Model (1967, 1970) generated an equilibrium by maximizing entropy of trips, goods flows or the distribution of population. This model assumes a perfect equilibrium, which may never be reached in reality. Anas’ (1982) model called Residential Location Markets and Urban Transportation created an equilibrium between demand, supply and costs for housing. Anas’ model, rather than follow the traditional deterministic approach that assigns each dwelling to the highest-paying buyer, instead applies stochastic variation to preferences and decisions.

The MEPLAN model developed by Echenique is an aggregated land-use transport model (Echenique et al., 1969, Echenique et al., 1990, Abraham and Hunt, 1999) that used the basic concept of the Lowry model as a starting point. The model can simulate a variety of both land-use and transport scenarios. MEPLAN has been applied to more than 25 regions worldwide (Hunt et al., 2005: 332). Another modeling approach using the Lowry model as a starting point is the TRANUS model (de la Barra, 1989: 143 ff, de la Barra and Rickaby, 1982, de la Barra et al., 1984) that simulates land use, transport, and its interactions at the urban and regional scale.

Martínez (2002, 1996) developed a land-use model under the acronym MUSSA in which location choice is modeled as a static equilibrium. Residential and commercial land-use developments compete for available land. MUSSA used the bid-auction approach based on the bid-rent theory where consumers try to achieve prices as low as possible and not higher than their willingness to pay (Martínez, 1992). In the bid-rent theory, first introduced by Alonso (1964: 36 ff), land prices are an immediate result of the bid-auction process. In contrast, the discrete-choice approach initially developed for housing choice by McFadden (1978: 76 ff)- models land being bought or rented with no instant effect on the price. Acknowledging that both approaches lead to similar results, Martínez argues elsewhere (1992: 884 f) that the bid-auction approach and the discrete-choice approach should be integrated and seen as inseparable rather than opposed.

Wegener (1999, 1998b, 1982) developed the IRPUD model as a fully integrated land-use transport model. The household location choice is microscopic (Wegener, 1984), simulating every household individually. The IRPUD model was one of the few early approaches that contradicted the common assumption that land-use models shall reach an equilibrium at the end of each simulation period (Wegener et al., 1986). Land-use development aims at equilibrium constantly, but due to a continuously changing environment and slow reaction times of households, businesses, developers and planners, this equilibrium stage is never reached. The price of a new dwelling and the commute distance to the household’s main workplace are accounted for as true constraints in location choice. Similarly, the Metroscope model for Portland, Oregon (Conder and Lawton, 2002) compares expenditures for housing, transportation, food, health and all other expenses to ensure that household budgets are not exceeded.
PECAS (Hunt and Abraham, 2009, 2003) is another land use model that represents an equilibrium of competing demand for developable land. Households relocate based on available floorspace, prices, accessibilities and other location factors. PECAS combines this bid-rent approach in a spatial economic model with a microscopic land development model. DELTA (Simmonds and Feldman, 2007) combines an economic model with households and job location model and a long-distance migration model.

Microsimulation was introduced by Orcutt (1961: 45 ff.) and subsequently applied to a series of modeling tasks, including travel behavior, demographic change, spatial diffusion, health and land use (Clarke and Holm, 1987: 156 ff.). The most influential microscopic land use models include the California Urban Futures (CUF) Model (Landis and Zhang, 1998a, 1998b), the Integrated Land Use, Transport and Environment (ILUTE) model (Miller et al., 2004, Miller and Salvini, 2001, Salvini and Miller, 2003), the Urban Simulation (UrbanSim) model (Waddell, 2002, Waddell et al., 2003), the Learning-Based Transportation Oriented Simulations System (ALBATROSS) (Arentze and Timmermans, 2000), Predicting Urbanisation with Multi-Agents (PUMA) (Ettema et al., 2004), SimDELTA (Simmonds and Feldman, 2007) and the Integrated Land-Use Model And transportation System Simulation (ILUMASS) (Strauch et al., 2005, Wagner and Wegener, 2007). A common problem in microscopic modeling is stochastic variability between model runs. Gregor (2006) overcame this shortcoming in the Land Use Scenario DevelopeR (LUSDR) by running the same model hundreds of times and store each model run as a potential future development.

Good overviews of operational land-use/transport models are given particularly by Hunt et al. (2005), Wegener (2004, 1998a, 1994), Wegener and Fürst (1999: 42 ff), Timmermans (2003), Kanaroglou and Scott (2002), the U.S. Environmental Protection Agency EPA (2000: 27 ff), and Kain (1987). The literature review showed that most land use models do not explicitly represent constraints. The majority of models employ equilibrium methods to reach an “ideal” distribution of households and land uses. Commonly, land use is viewed as a decision-making process in which users optimize their utilities, rather than making choices among a limited set of alternatives. Notable exceptions are the IRPUD model and Metroscope, which explicitly constrain households to move to dwellings that are within their respective price range.

3 The land use model SILO

SILO was designed as a microscopic discrete choice model. Every household, person and dwelling is treated as an individual object. All decisions that are spatial in nature (household relocation and development of new dwellings) are modeled with Logit models. Initially developed by Domencich & McFadden (1975), such models are particularly powerful at representing the psychology behind decision making
under uncertainty. Other decisions (such as getting married, giving birth to a child, leaving the parental household, renovating a dwelling, etc.) are modeled with Markov models by applying transition probabilities.

SILO is integrated with the Maryland Statewide Transportation Model (MSTM) to fully represent interactions between land use and transportation. The model is built to work with less rigorous data collection and estimation requirements than traditional large-scale land-use models. Rather than requiring costly data collection and time-consuming model estimation, SILO takes advantage of national averages where possible and transfers parameters from models that have been implemented elsewhere. Figure 1 provides an overview of the SILO model.

![Flowchart of the land use model SILO](image)

At the beginning, a synthetic population is created for the base year 2000. The U.S. Census Public Use Micro Sample (PUMS) 5% dataset\(^2\) is used to create this synthetic population. Using expansion factors provided by PUMS, household records including their dwelling are duplicated until the population by PUMS zone (called a PUMA) matches 2000 census data. The location is disaggregated from PUMA to model zones using the zonal socio-economic data of the MSTM as weights. Work places are created based on MSTM zonal employment data. For each worker, a work location is chosen within the recorded work-PUMA and based on the average commute trip length distribution found in the 2007-2008 Household Travel Survey for the Baltimore/Washington region. SILO simulates events that may occur to persons, households and dwellings:

### Household
- Relocation
- Buy or sell cars

### Person
- Aging
- Divorce
- Leave parental household
- Death
- Marriage
- Find a new job
- Birth to a child
- Quit a job

### Dwelling
- Construction of new dwellings
- Demolition
- Renovation
- Increase or decrease of housing price
- Deterioration

The housing market is modeled explicitly. Vacancy rates by five dwelling types and 31 regions are used as a proxy for additional demand. If vacancy rates drop, developers will add additional dwellings if zoning permits. To find the best locations for new dwellings, developers mimic the location choice behavior of households, and thereby, developers are likely to build the most marketable new dwellings. New dwellings are released into the housing market with a one-year delay to account for time required for planning, approval and construction. A hedonic price model is used to model changes in housing costs. Low vacancy rates lead to a fairly quick upward adjustment of prices, while high vacancies lead to a gradual price reduction. This reflects observed behavior that landlords attempt to keep prices high, even if demand is rather low.

From one year to the next, certain events may trigger other events. For example, if a child is born, the household will have a higher probability to move to a larger dwelling. Within one year, however, events are modeled in random order to avoid path dependency. A random number is assigned to each event, events are sorted by this number in ascending order and executed in this sequence.

SILO is set to match observed land use changes from 2000 to 2012 (so-called back-casting), and validated in 2012. Currently, the model runs to 2040. While the entire model is fully operational, the remainder of this paper focuses on household relocation for which constraints are implemented explicitly.

The model covers demographic changes, household relocation and real estate changes. Workplaces and commercial floorspace are not modeled explicitly at this point but exogenously given based on the Financially Constrained Long-Range Transportation Plan (CLRP). In the future, it is planned to add a submodel that simulates the employment side.

SILO is open-source software and was initially developed with research funding by Parsons Brinckerhoff, Inc. The prototype application was implemented for the
Metropolitan Area of Minneapolis/St. Paul, Minnesota. Currently, the Maryland Department of Transportation supports the implementation of an improved version for the State of Maryland. The acronym stands for Simple Integrated Land Use Orchestrator, as the model is meant to be implemented more easily than traditional large-scale models that require extensive model estimation. A visualization tool is included for the analysis of model results. Further information on model design and implementation can be found at www.silo.zone.

4 Modeling constraints

SILO distinguishes location factors that are desirable and those that are essential. Finding a place to live within someone’s housing budget, for example, is considered to be an essential location factor. Having a particularly large apartment, on the other hand, is a desirable location factors only. If all other location factors are excellent, a household might compromise dwelling size.

In contrast to desirable utilities, essential utilities are assumed to be mandatory to be fulfilled. The three essential location factors represented by SILO include housing costs, commute travel times and transportation costs. If one of these three utilities is 0, the utility for the entire dwelling has to be 0. This is achieved by using the Cobb-Douglas function that aggregates utilities by multiplication.

\[
ud = util_{pd}^a \cdot util_{ctd}^b \cdot util_{tbd}^r \cdot util_{desFacd}^{(1-a-b-r)}
\]

where:
- \(ud\) Utility of dwelling \(d\)
- \(util_{pd}\) Utility of the price \(p\) of dwelling \(d\) (see section 4.1)
- \(util_{ctd}\) Utility of the commute time \(ct\) from dwelling \(d\) (see section 4.2)
- \(util_{tbd}\) Utility of the transportation budget \(tb\) required for dwelling \(d\) (see section 4.3)
- \(util_{desFacd}\) Utility of non-essential factors of dwelling \(d\) (see section 4.4)
- \(a, b, r\) Parameters as weights for each factor, set differently by household type

This way, it is ensured that households do not move into a place that violates a budget constraint. The following sections describe the three essential location factors (sections 4.1 to 4.3) and desirable location factors (section 4.4).

4.1 Housing cost constraints

The costs of a dwelling form an immediate constraint for any relocation choice. While households may exceed their housing budget temporarily, households have to get along with their income in the long run. The distribution of rent and mortgage payments in the base year according to PUMS data is used as guidance on how much households are willing to pay for housing. Figure 2 shows the aggregation to reveal
the willingness to pay rent or to pay for a mortgage. As expected, higher income households tend to pay more for housing than low-income households.

Figure 2: Willingness to pay rent by household income (Source: PUMS 2000 database)

The relationship between income and housing expenses shown in Figure 2 is used to calculate the utility of a given price using equation 2.

\[ util_{pd} = 1 - \sum_{price_j}^{{price_\text{<price}_j}} hhShare_{price_j, inc} \]

Equation 2

where:
- \( util_{pd} \) Utility of price \( p \) of dwelling \( d \)
- \( hhShare_{price_j, inc} \) Share of households with income \( inc \) who have paid \( price_j \) in the base year

The higher the price, the lower the utility, and the utilities decline faster for low-income households than for high-income households. When the price is as high that the share of households paying this amount for housing reaches zero, the utility becomes zero and that dwelling becomes unavailable for this household type.

4.2 Commute travel time constraint

The travel time to work is a primary driver for household location choice. With the exception of workers who regularly work from home, the travel time from home to work is an important constraint when choosing a new place to live. Travel time to work is remarkably constant over time (Zahavi et al., 1981, van Wissen et al., 1991). The aforementioned household travel survey for the Baltimore/Washington region was analyzed for the time spent on home-to-work trips. Because respondents tend to round their travel time to even numbers (for example, 12 percent reported their commute to be exactly 30 min), the observed trip length frequency distribution is
lumpy and needs to be interpolated. Figure 3 shows the estimated gamma functions representing the observed trip length frequency distribution in minutes for commute trips. The gamma functions were calibrated to match the reported average travel time.

Residents living in the urban counties in Baltimore, Washington, Arlington and Alexandria have above-average commute times. Even though their average commute trip lengths of 9.8 miles is shorter than the average commute trip length of outer suburbs residents (15.5 miles), urban densities lead to more congestion, and therefore, residents need more time to get to work. Also, the transit share is much higher in urban areas, which often leads to longer travel times. The trip length frequency distributions in minutes are expected to not change significantly in the future.

When households look for a new housing location, the job locations of all household members are taken into account. As SILO is designed as a microsimulation, the work locations of all household members are known. Dwellings that would result in a commute of more than 200 minutes for any worker in a household are given a utility of zero. It was confirmed with the survey that the average travel time per worker is almost identical (within 3%) for single-worker households and multiple-worker households, allowing to apply the same trip length frequency distribution probabilities for all households. The left map in Figure 4 shows an example of a work location in North Bethesda, MD (turquoise dot). The trip length frequency
distribution in minutes is used to estimate the utility in terms of commute distance for every zone (shown in brown-to-yellow colors).

![Figure 4: Likely housing locations for a household with workers in North Bethesda (left), Columbia (center) and both work locations (right)](image)

The map in the center shows the home location probability for a person working in Columbia, MD. If these two persons lived in the same household, their joint area within a reasonable distance to their work locations is shown in the map on the right side of Figure 4. SILO explicitly represents this constraint when searching for a new housing location. The average commute trip length frequency in minutes shown in Figure 3 with a dotted line is scaled to values between 0 and 1 and applied as the commute distance utility.

Unfortunately, telework is not represented explicitly in SILO at this point. An employee working from home a few days per week is likely to be less constrained by the location of her or his employer and willing to accept longer commute travel times for the few days this person is actually commuting to work. It is planned to enhance the model to allow certain occupations types to telecommute, and thereby, offset some of their travel time budget.

Another shortcoming worth mentioning is that the constant travel time budget seems only to be reasonable with conventional modes of transportation. Should driverless cars become widely available, the value of time is expected to change substantially (Cyganski et al., 2015). Traveling in driverless cars may lessen the burden of commuting and thereby reduce this constraint in housing location in the future.

4.3 Household budget constraint

Another constraint explicitly reflected in SILO covers household expenditures. According to the Consumer Expenditure Survey\(^3\) of the Bureau of Labor Statistics, households spent an average of 18.2 percent of their after-tax income on transportation (fixed and variable costs) in 2000. Low-income households spent as

\(^3\) Data available online at http://www.bls.gov/cex/home.htm
much as 36.1 percent of their after-tax income on transportation. If transportation costs rise, those households will need to shift some expenses. While affluent households will simply reduce savings or discretionary spending to cover increased transportation costs, low-income households may struggle to cover substantially higher transportation costs. A household searching for a new home will at least roughly estimate transportation costs and consider carefully if transportation costs at a given home location are within the budget. A low-income household may decide to locate closer to the work location or choose a transit-friendly environment that may allow reducing the number of cars owned by the household.

Figure 5 compares average household income with average expenditures. The plot shows data for SILO’s base year 2000, data for 2005 and 2010 were analyzed and displayed very similar patterns. Interestingly, households in income categories with an annual after-tax income below $41,500 spent on the average more money than they earned. According to the BLS, such households draw on savings or borrow money. Students may get by on loans and retirees may rely on savings. As SILO does not trace debts a household may temporarily accumulate, it simply acknowledges that households have access to money to cover their expenses. For example, a household with an after-tax income of $7,192 (left-most point in Figure 5) is assumed to have access to $15,703 to spend.

A polynoninal curve has been estimated to reflect the relationship between income and expenditures (shown with a red dashed line in Figure 5). For household

\[\text{Figure 5: Household income and expenditures (Source: Consumer Expenditure Survey, BLS)}\]

\[\text{A polynominal curve has been estimated to reflect the relationship between income and expenditures (shown with a red dashed line in Figure 5). For household}\]

\(^4\) For a more detailed discussion of this phenomenon compare http://www.bls.gov/cex/csxfaqs.htm#q21
incomes greater than $41,499 (whose income exceeds expenditures), the entire income is assumed to be available for expenditures, even though the average household at that income level saves some money.

\[ e_h = \max \left[ inc_h \left( \alpha \cdot inc_h^2 + \beta \cdot inc_h + \gamma \right) \right] \]  

Equation 3

where:

- \( e_h \): Budget available for expenditures of household \( h \)
- \( inc_h \): Income of household \( h \)
- \( \alpha, \beta, \gamma \): Parameters, estimated to \( \alpha = -2E-6, \beta = 0.8229 \) and \( \gamma = 10,794 \)

[note that parameter names \( \alpha, \beta \) and \( \gamma \) are reused in several equations even though they relate to different parameter sets]

Due to the parameter \( \gamma \), the available money for expenditures can never drop below $10,794, even if the household income is reported as 0. According to the Consumer Expenditure Survey, expenses for gasoline and motor oil make up between 2.6 percent (for high income) and 3.9 percent (for low income) of all household expenses. Though this may not seem high, an increase of travel costs may become a serious burden for low-income households. Litman (2013) suggested that fuel price elasticity is between -0.1 and -0.2 for short run and between -0.2 and -0.3 for medium run adjustments. Short-run adjustments include choosing different trip destinations and switching the mode, while long-run adjustments (which typically apply after one to two years) include the purchase of more fuel-efficient vehicles and selecting more accessible home and job locations. Because a household move is part of a medium- to long-run adjustment, the higher elasticity with an average of -0.25 was chosen in SILO: Should gas prices increase by 10 percent, travel demand is expected to decline by 2.5 percent. Transportation costs \( tc \) are calculated based on auto-operating costs (set to 8.1 cents per mile in the base scenario), the distance to work, and transportation required for other purpose, such as shopping, dropping off children at childcare, doctor visits, etc. For a scenario that analyzes the impact of higher fuel costs, the adjusted transportation expenditures are calculated by

\[ et_h = tc_s \left( 1 + \frac{tc_r - tc_r}{tc_r} \cdot el \right) \]  

Equation 4

where:

- \( et_h \): Expenditures of household \( h \) for transportation
- \( tc \): Transportation costs (\( r \) for reference case and \( s \) for alternative scenario)
- \( el \): Elasticity of travel demand on transportation costs, set to -0.25

Currently, the elasticity is held constant, even though it is commonly assumed that elasticities rise as fuel prices increase. However, no data were readily available to quantify this relationship. Depending on future improvements in vehicle technology, the price per mile might drop, though increasing energy prices may offset technological advances. Currently, transportation costs per mile are kept unchanged from 2000 to 2040.
Costs for transit are not considered at this point, but auto travel costs are used as a proxy for the costs transit riders would face. This simplification is used for two reasons. First, the MSTM does not provide reliable transit fare values. In the future, General Transit Feed Specification (GTFS) data are planned to replace existing transit networks, which is expected to overcome this shortcoming. Secondly, SILO does not know which mode of transport is going to be used by each traveler in the MSTM. While assumptions for zero-car households are easy (most of them will use transit), modal predictions for other households are difficult. However, given that transit operating costs are considered to be comparatively high in this region, the auto operating costs appear to be a reasonable proxy for transportation costs even for transit riders.

In addition to adjusting travel behavior and locations, many households will need to rebalance expenditures if transportation costs rise. Figure 6 shows the relative size of various expenditure types. The total expenditure is identical to the expenditure line shown in Figure 5, and the shares of various expenditure categories were also estimated by polynominal functions using observations of the Consumer Expenditures Survey. A certain share of “Other expenditures” is assumed to be discretionary (such as going out for dinner, going to the movie theater, vacationing, etc.) and could be used to offset increased transportation costs. No data were available to quantify discretionary spending, and a few data points5 were assumed to estimate a smooth curve for the discretionary spending shown in Figure 6.

---

5 Assumed data points for Income/discretionary spending: [$0/$100; $20,000/$1,000; $40,000/$2,200; $100,000/$10,000; $150,000/$20,000]
A binomial logit model (equation 5) is used to calculate the utility for transportation costs. If the discretionary income and savings are insufficient to cover the transportation costs of a given dwelling, the utility for transportation costs at this dwelling is set to 0.

\[
\begin{align*}
\text{if } (e_{dis,h} + s_h < tc): \quad \text{util}_{d} &= 0 \\
\text{if } (e_{dis,h} + s_h \geq tc): \quad \text{util}_{d} &= \frac{1}{1 + \exp\left(\beta \cdot \frac{e_{dis,h} + s_h}{tc}\right)} \\
\end{align*}
\]

Equation 5

where:
- \(\text{util}_{d}\) Utility of dwelling \(d\) for transportation budget \(tb\)
- \(\beta\) Parameters describing sensitivity of increased transportation costs
- \(e_{dis,h}\) Discretionary expenditures of household \(h\)
- \(s_h\) Savings of household \(h\)

For high-income households, this utility will always be close to 1, as an increase in transportation costs is insignificant for these households. Households with a lower income, however, will find a lower utility if transportation costs at a given dwelling are high. Should transportation costs exceed the discretionary income plus savings, the utility for the dwelling will be set to 0, which prevents this household from moving into this dwelling.
4.4 Desirable location factors

In addition to housing costs, commute travel times and transportation costs (described sections 4.1 to 4.3), a number of further location attributes are included that are deemed to be desirable but non-essential. Such location factors include the size and the quality of the dwelling, the accessibility to population and employment by auto and transit, low crime rates and the quality of schools in the school district of a dwelling. While these location factors are desirable, one strong attribute may compensate for another weak attribute. For example, a house in the suburbs may be weak in terms of accessibility but strong in terms of size. In contrast, urban apartments tend to be weaker in size but provide excellent accessibilities. A strong attribute may offset a weak attribute, depending on the household preferences. Those location factors are combined by weighted addition.

\[
\text{util}_{\text{desFac}} = \alpha \cdot \text{size} + \beta \cdot \text{quality} + \gamma \cdot \text{autoAccess} + \delta \cdot \text{transitAccess} + \epsilon \cdot \text{schoolQuality} + (1 - \alpha - \beta - \gamma - \delta - \epsilon) \cdot \text{util\_crimeIndex} \quad \text{Equation 6}
\]

where:
- \(\text{util}_{\text{desFac}}\): Utility of desirable (but non-essential) factors for dwelling \(d\)
- \(\alpha, \beta, \gamma, \ldots\): Parameters, set differently by household types
- \(\text{util\_factor}\_d\): Utility of attribute of dwelling \(d\) (currently implemented: size, quality, auto accessibility, transit accessibility, school quality and county-level crime index)

5 Sensitivity Testing and Model Validation

Validating land use models tends to be more challenging than validating transportation models. While counts are generally perceived as sufficiently accurate to validate transportation models, no comparable dataset exists for land use models. Two approaches were applied to validate SILO. First, sensitivity tests were conducted in which single parameters were modified and the changed model results were analyzed for reasonability. This is not considered to be a true validation in the traditional sense of comparing observed with modeled data, but it is rather a reasonability check. Such sensitivity tests have been completed for many variables, including parameters to calculate housing utilities, marriage and divorce probabilities, probability to leave the parental household, birth probabilities, initial housing vacancy rates, immigration and outmigration assumptions, land capacity for future development, accessibility parameters and auto-operating costs. Changes in model results were small and moved in the expected direction of change.

Secondly, rather than starting the model in a current base year, “back-casting” from 2000 to 2012 was applied. Figure 7 shows a scatter plot that compares observed and modeled number of households by county (\(R^2 = 0.991, \text{RMSE} = 10,107, \text{Percent RMSE} = 12.6\%\)). Modeled population numbers are the result of simulating 12 years in one-year increments, and observed population was collected from the 5-year population estimate of the American Community Survey (ACS). Several counties in Maryland are slightly overestimated by the model, while Fairfax County (including
Fairfax City and Falls Church City) falls short by 10 percent. This deviation along the state line is largely due to the fact that Maryland and Virginia have different methodologies of accounting for redevelopment opportunities (including greenfield development and infill development). Maryland traditionally has promoted denser development and has provided higher development capacity numbers than Virginia. Hence, the model expects more opportunities for growth in Maryland than in Virginia. It is investigated currently whether development capacities can be calculated by a unique method for the entire study area.

Figure 7: Validation of SILO results against 2012 ACS population data by county

SILO results were also compared at the zonal level against 2012 data from transportation models for Baltimore, Washington and Delaware. At this zonal level, an RMSE of 1,123 and a Percent RMSE of 9% were found. The provenance of their zonal data is unknown, which is why this comparison does not count as validation but only as another reasonability check.

6 Conclusions

Many land-use models focus on representing utility maximization, finding equilibriums and optimally allocating limited resources. The famous Lowry model was built to reach an equilibrium between location of work places and location of households every simulation period (Lowry, 1964). Similarly, most models using Alonso’s bid-rent approach (Alonso, 1964) assume an immediate equilibrium between land prices and demand for land. Dynamic urban models, in contrast,
explicitly represent time delay and limited information that lead to imperfect equilibriums (Harris and Wilson, 1978, Wegener, 1986). While bid-rent models are assumed to better represent land prices, discrete choice models often are expected to more realistically represent delays as they happen in reality. For example, newly demanded housing is not available to move in right away, but planning, obtaining building permits and construction may take more than a year from when the demand is realized to when the first household may move in.

Wegener (2014: 753-755) identified three principal challenges for land-use modeling: represent environmental impacts, decline rather than growth, and the impacts of the future energy crises. Testing policies that address environmental impacts, such as carbon taxes, road pricing or energy-efficient buildings has an immediate impact on household budgets. Planning for decline requires reallocating limited resources, including closing of schools or redevelopment of brownfield sites. A future energy crisis may limit the availability of fossil fuels for transportation or heating and cooling, with an immediate impact on household mobility and budgets. If these challenges hold true, representing constraints will become even more important. If models miss representing changes in travel behavior and location choice under increasing transportation costs, model results will be less realistic and difficult to defend. If congestion worsens and people spend more time traveling, models that miss adjusting destination choice, mode choice and trip chaining will produce unlikely results. Representing constraints rather than the entire map of opportunities will become more important in a scarce energy future.

7 Acknowledgement

This research was funded in part by the Maryland Department of Transportation. An earlier version of SILO was developed with research funding of Parsons Brinckerhoff, Inc. Important input for model design and development were provided by Rick Donnelly, Greg Erhardt and Chris Frazier.
